14.03

can we have unions inside a unions yes.
nested unions possible.
unions inside a structure yes
structures inside a union yes

can we have selfereferential unions
Syntaically valid , but practically no use.

sizeof empty structure is zero bytes.

enumerator(enum)

enum is a userdefined datatype , which is use to give names to integer constant , so that readability of the program can be increased

by default enum member takes zero as value.
enum members does not occupy any memory.they are not strings
they are not avariables , they are just names to integer constants

Points to be noted :
enum members can be initialised with random values.
we cannot give same name to more than one constant.
we can have same value to more than one enum member.
we cannot chnage the value of enum member outside the declaration.

enum Vs macros:

1. enum belongs to compilation stage	macros belongs to preprocessor stage
2. enums are names given only to integer constant	macros are used with anytype of data, as wellas identifiers and alos with datatype
3. enum follows scope rules	macros does not follow any scope
4. enum will not replace	macros get replaced

5. enums are declared in a single statement	macros need to define individually
6. enum by default assign zero to its first member	macros will not assign any default value
7. enums cannot be undefined	macros can undefined them

enums are used in Calender applications
